## Abstract

The stability of a complex system generally decreases with increasing system size and interconnectivity, a counterintuitive result of widespread importance across the physical, life, and social sciences. Despite recent interest in the relationship between system properties and stability, the effect of variation in the response rate of individual system components remains unconsidered. Here I vary the component response rates ( $\gamma$ ) of randomly generated complex systems. I use numerical simulations to show that when component response rates vary, the potential for system stability is markedly increased. These results are robust to common network structures, including small-world and scale-free networks, and cascade food webs. Variation in  $\gamma$  is especially important for stability in highly complex systems, in which the probability of stability would otherwise be negligible. At such extremes of simulated system complexity, the largest stable complex systems would be unstable if not for  $\text{Var}(\gamma)$ . My results therefore reveal a previously unconsidered aspect of system stability that is likely to be pervasive across all realistic complex systems.

## 19 Introduction

20 In 1972, May<sup>1</sup> first demonstrated that randomly assembled systems of sufficient complexity are almost  
21 inevitably unstable given infinitesimally small perturbations. Complexity in this case is defined by the  
22 size of the system (i.e., the number of potentially interacting components;  $S$ ), its connectance (i.e., the  
23 probability that one component will interact with another;  $C$ ), and the variance of interaction strengths  
24 ( $\sigma^2$ )<sup>2</sup>. May's finding that the probability of local stability falls to near zero given a sufficiently high threshold  
25 of  $\sigma\sqrt{SC}$  is broadly relevant for understanding the dynamics and persistence of systems such as ecological<sup>1-5</sup>,  
26 neurological<sup>6,7</sup>, biochemical<sup>8,9</sup>, and socio-economic<sup>10-13</sup> networks. As such, identifying general principles that  
27 affect stability in complex systems is of wide-ranging importance.

28 Randomly assembled complex systems can be represented as large square matrices ( $\mathbf{M}$ ) with  $S$  components  
29 (e.g., networks of species<sup>2</sup> or banks<sup>11</sup>). One element of such a matrix,  $M_{ij}$ , defines how component  $j$   
30 affects component  $i$  in the system at a point of equilibrium<sup>2</sup>. Off-diagonal elements ( $i \neq j$ ) therefore define  
31 interactions between components, while diagonal elements ( $i = j$ ) define component self-regulation ( $d$ , e.g.,  
32 carrying capacity in ecological communities). Traditionally, off-diagonal elements are assigned non-zero values  
33 with a probability  $C$ , which are sampled from a distribution with variance  $\sigma_M^2$ ; diagonal elements are set to  
34  $d = -1$ <sup>1,2,4</sup>. Local system stability is assessed using eigenanalysis, with the system being stable if the real  
35 parts of all eigenvalues ( $\lambda$ ) of  $\mathbf{M}$  are negative ( $\max(\Re(\lambda)) < 0$ )<sup>1,2</sup>. In a large system (high  $S$ ), eigenvalues are  
36 distributed uniformly<sup>14</sup> within a circle centred at  $\Re = -1$  (the mean value of diagonal elements) and  $\Im = 0$ ,  
37 with a radius of  $\sigma_M\sqrt{SC}$ <sup>1,2,4</sup> (Figs 1a and 2a). Local stability of randomly assembled systems therefore  
38 becomes increasingly unlikely as  $S_M$ ,  $C_M$ , and  $\sigma_M^2$  increase.

39 May's<sup>1,2</sup> stability criterion  $\sigma_M\sqrt{SC} < 1$  assumes that the expected response rates ( $\gamma$ ) of individual components  
40 to perturbations of the system are identical, but this is highly unlikely in any complex system. In ecological  
41 communities, for example, the rate at which population density changes following perturbation will depend  
42 on the generation time of organisms, which might vary by orders of magnitude among species. Species with  
43 short generation times will respond quickly (high  $\gamma$ ) to perturbations relative to species with long generation

times (low  $\gamma$ ). Similarly, the speed at which individual banks respond to perturbations in financial networks, or individuals or institutions respond to perturbations in complex social networks, is likely to vary. The effect of such variance on stability has not been investigated in complex systems theory. Intuitively, variation in  $\gamma$  ( $\sigma_\gamma^2$ ) might be expected to decrease system stability by introducing a new source of variation into the system and thereby increasing  $\sigma_M$ . Here I show that, despite higher  $\sigma_M$ , realistic complex systems (such that  $S$  is high but finite) are actually more likely to be stable if their individual component response rates vary. My results are robust across commonly observed network structures, including random<sup>1</sup>, small-world<sup>15</sup>, scale-free<sup>16</sup>, cascade food web<sup>17</sup> networks.

## Results

**Component response rates of random complex systems.** Complex systems  $\mathbf{M}$  are built from two matrices, one modelling component interactions ( $\mathbf{A}$ ), and second modelling component response rates ( $\gamma$ ). Both  $\mathbf{A}$  and  $\gamma$  are square  $S \times S$  matrices. Rows in  $\mathbf{A}$  define how a given component  $i$  is affected by each component  $j$  in the system, including itself (where  $i = j$ ). Off-diagonal elements of  $\mathbf{A}$  are independent and identically distributed (i.i.d), and diagonal elements are set to  $A_{ii} = -1$  as in May<sup>1</sup>. Diagonal elements of  $\gamma$  are positive, and off-diagonal elements are set to zero (i.e.  $\gamma$  is a diagonal matrix with positive support). The distribution of  $\gamma$  over  $S$  components thereby models the distribution of component response rates. The dynamics of the entire system  $\mathbf{M}$  can be defined as follows<sup>18</sup>,

$$M = \gamma A. \tag{1}$$

Equation 1 thereby serves as a null model to investigate how variation in component response rate ( $\sigma_\gamma$ ) affects complex systems. In the absence of such variation ( $\sigma_\gamma = 0$ ),  $\gamma$  is set to the identity matrix (diagonal elements all equal 1) and  $\mathbf{M} = \mathbf{A}$ .

**Analytical considerations.** The value of  $\max(\Re(\lambda))$ , and therefore system stability, can be estimated from

65 five properties of  $\mathbf{M}$ <sup>19</sup>. These properties include (1) system size ( $S$ ), (2) mean self-regulation of components  
 66 ( $d$ ), (3) mean interaction strength between components ( $\mu$ ), (4) the standard deviation between component  
 67 interaction strengths ( $\sigma_M$ ), and (5) the correlation of interaction strengths between components,  $M_{ij}$  and  
 68  $M_{ji}(\rho)$ . Positive  $\sigma_\gamma$  does not change  $S$ , nor does it necessarily change  $E[d]$  or  $E[\mu]$ . What  $\sigma_\gamma$  does change is  
 69 the total variation in component interaction strengths ( $\sigma_M$ ), and  $\rho$ . Introducing variation in  $\gamma$  increases the  
 70 total variation in the system. Variation of the off-diagonal elements in  $\mathbf{M}$  is described by the joint variation  
 71 of two random variables,

$$\sigma_M^2 = \sigma_A^2 \sigma_\gamma^2 + \sigma_A^2 E[\gamma_i]^2 + \sigma_\gamma^2 E[A_{ij}]^2. \quad (2)$$

72 Given  $E[\gamma_i] = 1$  and  $E[A_{ij}] = 0$ , equation 2 can be simplified,

$$\sigma_M^2 = \sigma_A^2 (1 + \sigma_\gamma^2). \quad (3)$$

73 The increase caused by  $\sigma_\gamma^2$  can be visualised from the eigenvalue spectra of  $\mathbf{A}$  versus  $\mathbf{M} = \gamma\mathbf{A}$  (Figure 1).  
 74 Given  $d = 0$  and  $C = 1$ , the distribution of eigenvalues of  $\mathbf{A}$  and  $\mathbf{M}$  lie within a circle of a radius  $\sigma_A^2 \sqrt{S}$  and  
 75  $\sigma_M^2 \sqrt{S}$ , respectively (Figure 1a vs. 1b). When components are self-regulating (e.g.,  $d = -1$ ), positive  $\sigma_\gamma^2$   
 76 changes the distribution of eigenvalues, potentially affecting stability (Figure 1c vs. 1d).

77 Given  $\sigma_\gamma^2 = 0$ ,  $\max(\Re(\lambda))$  decrease linearly with  $\rho$  such that,

$$\max(\Re(\lambda)) \approx \sigma_M \sqrt{SC} (1 + \rho). \quad (4)$$

78 When  $\rho$  values are negative, such as when  $\mathbf{M}$  models a predator-prey system in which  $M_{ij}$  and  $M_{ji}$  have  
 79 opposing signs, stability is expected to increase<sup>2</sup>. When elements of  $\gamma$  vary independently, the magnitude of  $\rho$   
 80 is decreased because  $\sigma_\gamma^2$  increases the variance of  $M_{ij}$  without affecting the covariance between  $M_{ij}$  and  $M_{ji}$ ,

$$\rho = \frac{\text{cov}(M_{ij}, M_{ji})}{\sigma_A^2(1 + \sigma_\gamma^2)}. \quad (5)$$

Because  $\gamma$  does not affect  $\text{cov}(M_{ij}, M_{ji})$ , the sign of  $\rho$  remains unchanged.

**Numerical simulations.** I used numerical simulations to isolate the effect of  $\sigma_\gamma$  on the stability of  $\mathbf{M} = \gamma\mathbf{A}$  by comparing  $\sigma_\gamma > 0$  versus  $\sigma_\gamma = 0$ . Values of  $\gamma_{ii}$  were sampled such that  $E[d]$  and  $E[\mu]$  also remained unchanged (in practice, diagonal elements of  $\mathbf{M}$  were standardised so that mean values were identical before and after adding  $\gamma$ ).

Higher stability in systems with variation in  $\gamma$  can be observed by sampling  $\gamma_i$  values from various distributions. I focus on a uniform distribution where  $\gamma \sim \mathcal{U}(0, 2)$  (see Supplementary Information for other distributions, which give similar results). As with the case of  $\gamma = \{1.95, 0.5\}$  (Fig. 1b), mean  $\gamma = 1$  when  $\gamma \sim \mathcal{U}(0, 2)$ , allowing comparison of  $\mathbf{M}$  before and after the addition of variation in component response rate. Figure 2 shows a comparison of eigenvalue distributions given  $S = 1000$ ,  $C = 0.05$ , and  $\sigma = 0.4$ . As expected<sup>14</sup>, when  $\gamma = 1$ , eigenvalues are distributed uniformly in a circle centred at  $(-1, 0)$  with a radius of  $\sigma\sqrt{SC} = 2.828$ . Uniform variation in  $\gamma$  leads to a non-uniform distribution of eigenvalues<sup>20-22</sup>, some of which are clustered locally near the centre of the distribution, but others of which are spread outside the former radius of 2.828 (Fig 2b). The clustering and spreading of eigenvalues introduced by  $\text{Var}(\gamma)$  can destabilise previously stable systems or stabilise systems that are otherwise unstable. But where systems are otherwise too complex to be stable given  $\gamma = 1$ , the effect of  $\text{Var}(\gamma)$  can often lead to stability above May's<sup>1,2</sup> threshold  $\sigma\sqrt{SC} < 1$ .

**Simulation of random  $\mathbf{M}$  across  $\mathbf{S}$ .** To investigate the effect of  $\text{Var}(\gamma)$  on stability across systems of varying complexity, I simulated random  $\mathbf{M}$  matrices at  $\sigma = 0.4$  and  $C = 1$  across  $S = \{2, 3, \dots, 49, 50\}$ . One million  $\mathbf{M}$  were simulated for each  $S$ , and the stability of  $\mathbf{M}$  was assessed given  $\gamma = 1$  versus  $\gamma \sim \mathcal{U}(0, 2)$ . For all  $S > 10$ , I found that the number of stable random systems was higher given  $\text{Var}(\gamma)$  than when  $\gamma = 1$  (Fig. 3; see Supplementary Information for full table of results), and that the difference between the probabilities of observing a stable system increased with an increase in  $S$ . In other words, the potential for  $\text{Var}(\gamma)$  to affect stability increased with system complexity and was most relevant for systems on the cusp of being

too complex to be realistically stable. For the highest values of  $S$ , nearly all systems that were stable given  $Var(\gamma)$  would not have been stable given  $\gamma = 1$ .

**Targeted manipulation of  $\gamma$ .** To further investigate the potential of  $Var(\gamma)$  to be stabilising, I used a genetic algorithm. Genetic algorithms are heuristic tools that mimic evolution by natural selection, and are useful when the space of potential solutions (in this case, possible combinations of  $\gamma$  values leading to stability in a complex system) is too large to search exhaustively<sup>23</sup>. Generations of selection on  $\gamma$  value combinations to minimise  $\max(\Re(\lambda))$  demonstrated the potential for  $Var(\gamma)$  to increase system stability. Across  $S = \{2, 3, \dots, 39, 40\}$ , sets of  $\gamma$  values were found that resulted in stable systems with probabilities that were up to four orders of magnitude higher than when  $\gamma = 1$  (Fig. 4), meaning that stability could often be achieved by manipulating  $S$   $\gamma$  values rather than  $S \times S$   $\mathbf{M}$  elements (i.e., by manipulating component response rates rather than interactions between components).

**System feasibility given  $Var(\gamma)$**  For complex systems in which individual system components represent the density of some tangible quantity, it is relevant to consider the feasibility of the system. Feasibility assumes that values of all components are positive at equilibrium<sup>5,24,25</sup>. This is of particular interest for ecological communities because population density ( $N$ ) cannot take negative values, meaning that ecological systems need to be feasible for stability to be biologically realistic<sup>24</sup>. While my results are intended to be general to all complex systems, and not restricted to species networks, I have also performed a feasibility analysis on all matrices  $\mathbf{M}$  tested for stability, and additionally for specific types of ecological communities<sup>2</sup> (e.g., competitive, mutualist, predator-prey; see Supplementary Information). I emphasise that  $\gamma$  is not interpreted as population density in this analysis, but instead as a fundamental property of species life history such as expected generation time. Feasibility was unaffected by  $Var(\gamma)$  and instead occurred with a fixed probability of  $1/2^S$ , consistent with a recent proof by Serván et al.<sup>26</sup> (see Supplementary Information). Hence, for pure interacting species networks, variation in component response rate (i.e., species generation time) does not affect stability at biologically realistic species densities.

## Discussion

I have shown that the stability of complex systems might often be contingent upon variation in the response rates of their individual components, meaning that factors such as rate of trait evolution (in biological networks), transaction speed (in economic networks), or communication speed (in social networks) need to be considered when investigating the stability of complex systems. Variation in component response rate is more likely to be critical for stability in systems that are especially complex, and it can ultimately increase the probability that system stability is observed above that predicted by May's<sup>1</sup> classically derived  $\sigma\sqrt{SC}$  criterion. The logic outlined here is general, and potentially applies to any complex system in which individual system components can vary in their reaction rates to system perturbation.

It is important to recognise that variation in component response rate is not stabilising per se; that is, adding variation in component response rates to a particular system does not increase the probability that the system will be stable. Rather, highly complex systems that are observed to be stable are more likely to have varying component response rates, and for this variation to be critical to their stability (Fig. 3). This is caused by the shift to a non-uniform distribution of eigenvalues that occurs by introducing  $Var(\gamma)$  (Fig. 1b, 2b), which can sometimes cause all of the real components of the eigenvalues of the system matrix to become negative, but might also increase the real components of eigenvalues.

My focus is distinct from Gibbs et al.<sup>21</sup>, who applied the same mathematical framework to investigate how a diagonal matrix  $\mathbf{X}$  (equivalent to  $\gamma$  in my model) affects the stability of a community matrix  $\mathbf{M}$  given an interaction matrix  $\mathbf{A}$  within a generalised Lotka-Volterra model, where  $\mathbf{M} = \mathbf{XA}$ . Gibbs et al.<sup>21</sup> analytically demonstrated that the effect of  $\mathbf{X}$  on system stability decreases exponentially as system size becomes arbitrarily large ( $S \rightarrow \infty$ ) for a given magnitude of complexity  $\sigma\sqrt{SC}$ . My numerical results do not contradict this prediction because I did not scale  $\sigma = 1/\sqrt{S}$ , but instead fixed  $\sigma$  and increased  $S$  to thereby increase total system complexity (see Supplemental Information for results simulated across  $\sigma$  and  $C$ ). Overall, I show that component response rate variation increases the upper bound of complexity at which stability can be realistically observed, meaning that highly complex systems are more likely than not to vary

in their component response rates, and for this variation to be critical for system stability.

The potential importance of component response rate variation was most evident from the results of simulations in which the genetic algorithm was used in attempt to maximise the probability of system stability. The probability that some combination of component response rates could be found to stabilise the system was shown to be up to four orders of magnitude higher than the background probabilities of stability in the absence of any component response rate variation. Instead of manipulating the  $S \times S$  interactions between system components, it might therefore be possible to manipulate only the  $S$  response rates of individual system components to achieve stability. Hence, managing the response rates of system components in a targeted way could potentially facilitate the stabilisation of complex systems through a reduction in dimensionality.

Interestingly, while complex systems were more likely to be stable given variation in component response rate, they were not more likely to be feasible, meaning that stability was not increased when component values were also restricted to being positive at equilibrium. Feasibility is important to consider, particularly for the study of ecological networks of species<sup>5,22,24,26</sup> because population densities cannot realistically be negative. My results therefore suggest that variation in the rate of population responses to perturbation (e.g., due to differences in generation time among species) is unlikely to be critical to the stability of purely multi-species interaction networks (see also Supplementary Information). Nevertheless, ecological interactions do not exist in isolation in empirical systems<sup>18</sup>, but instead interact with evolutionary, abiotic, or social-economic systems. The relevance of component response rate for complex system stability should therefore not be ignored in the broader context of ecological communities.

A general mathematical framework encompassing shifts in eigenvalue distributions caused by a vector  $\gamma$  has been investigated<sup>20</sup> and recently applied to questions concerning species density and feasibility<sup>21,22</sup>, but  $\gamma$  has not been interpreted as rates of response of individual system components to perturbation. My model focuses on component response rates for systems of a finite size, in which complexity is high but not yet high enough to make the probability of stability unrealistically low for actual empirical systems. For this upper range of system size, randomly assembled complex systems are more likely to be stable if their component response rates vary (e.g.,  $10 < S < 30$  for parameter values in Fig. 3). Overall, I suggest that variation in component

response rate might therefore be critical for maintaining stability in many highly complex empirical systems. These results are broadly applicable for understanding the stability of complex networks across the physical, life, and social sciences.

## Methods

**Component response rate variation ( $\gamma$ ).** In a synthesis of eco-evolutionary feedbacks on community stability, Patel et al. model a system that includes a vector of potentially changing species densities ( $\mathbf{N}$ ) and a vector of potentially evolving traits ( $\mathbf{x}$ )<sup>18</sup>. For any species  $i$  or trait  $j$ , change in species density ( $N_i$ ) or trait value ( $x_j$ ) with time ( $t$ ) is a function of the vectors  $\mathbf{N}$  and  $\mathbf{x}$ ,

$$\frac{dN_i}{dt} = N_i f_i(\mathbf{N}, \mathbf{x}),$$

$$\frac{dx_j}{dt} = \epsilon g_j(\mathbf{N}, \mathbf{x}).$$

In the above,  $f_i$  and  $g_j$  are functions that define the effects of all species densities and trait values on the density of a species  $i$  and the value of trait  $j$ , respectively. Patel et al. were interested in stability when the evolution of traits was relatively slow or fast in comparison with the change in species densities<sup>18</sup>, and this is modulated in the above by the scalar  $\epsilon$ . The value of  $\epsilon$  thereby determines the timescale separation between ecology and evolution, with high  $\epsilon$  modelling relatively fast evolution and low  $\epsilon$  modelling relative slow evolution<sup>18</sup>.

I use the same principle that Patel et al. use to modulate the relative rate of evolution to modulate rates of component responses for  $S$  components. Following May<sup>1,27</sup>, the value of a component  $i$  at time  $t$  ( $v_i(t)$ ) is affected by the value of  $j$  ( $v_j(t)$ ) and  $j$ 's marginal effect on  $i$  ( $a_{ij}$ ), and by  $i$ 's response rate ( $\gamma_i$ ),

$$\frac{dv_i(t)}{dt} = \gamma_i \sum_{j=1}^S a_{ij} v_j(t).$$

196 In matrix notation<sup>27</sup>,

$$\frac{d\mathbf{v}(t)}{dt} = \gamma \mathbf{A} \mathbf{v}(t).$$

197 In the above,  $\gamma$  is a diagonal matrix in which elements correspond to individual component response rates.  
 198 Therefore,  $\mathbf{M} = \gamma \mathbf{A}$  defines the values of system components and can be analysed using the techniques  
 199 of May<sup>1,20,27</sup>. In these analyses, row means of  $\mathbf{A}$  are expected to be identical, but variation around this  
 200 expectation will naturally arise due to random sampling of  $\mathbf{A}$  off-diagonal elements and finite  $S$ . In simulations,  
 201 the total variation in  $\mathbf{M}$  row means that is attributable to  $\mathbf{A}$  is small relative to that attributable to  $\gamma$ ,  
 202 especially at high  $S$ . Variation in  $\gamma$  specifically isolates the effects of differing component response rates,  
 203 hence causing differences in expected  $\mathbf{M}$  row means.

204 **Genetic algorithm.** Ideally, to investigate the potential of  $Var(\gamma)$  for increasing the proportion of stable  
 205 complex systems, the search space of all possible  $\gamma$  vectors would be evaluated for each unique  $\mathbf{M} = \gamma \mathbf{A}$ .  
 206 This is technically impossible because  $\gamma_i$  can take any real value between 0-2, but even rounding  $\gamma_i$  to  
 207 reasonable values would result in a search space too large to practically explore. Under these conditions,  
 208 genetic algorithms are highly useful tools for finding practical solutions by mimicking the process of biological  
 209 evolution<sup>23</sup>. In this case, the practical solution is finding vectors of  $\gamma$  that decrease the most positive real  
 210 eigenvalue of  $\mathbf{M}$ . The genetic algorithm used achieves this by initialising a large population of 1000 different  
 211 potential  $\gamma$  vectors and allowing this population to evolve through a process of mutation, crossover (swapping  
 212  $\gamma_i$  values between vectors), selection, and reproduction until either a  $\gamma$  vector is found where all  $\Re(\lambda) < 0$  or  
 213 some “giving up” criteria is met.

214 For each  $S = \{2, 3, \dots, 39, 40\}$ , the genetic algorithm was run for 100000 random  $\mathbf{M}$  ( $\sigma = 0.4$ ,  $C = 1$ ). The  
 215 genetic algorithm was initialised with a population of 1000 different  $\gamma$  vectors with elements sampled i.i.d

from  $\gamma_i \sim \mathcal{U}(0, 2)$ . Eigenanalysis was performed on the  $\mathbf{M}$  resulting from each  $\gamma$  vector, and the 20  $\gamma$  vectors resulting in  $\mathbf{M}$  with the lowest  $\max(\Re(\lambda))$  each produced 50 clonal offspring with subsequent random mutation and crossover between the resulting new generation of 1000  $\gamma$  vectors. Mutation of each  $\gamma_i$  in a  $\gamma$  vector occurred with a probability of 0.2, resulting in a mutation effect of size  $\mathcal{N}(0, 0.02)$  being added to generate the newly mutated  $\gamma_i$  (any  $\gamma_i$  values that mutated below zero were multiplied by  $-1$ , and any values that mutated above 2 were set to 2). Crossover occurred between two sets of 100  $\gamma$  vectors paired in each generation; vectors were randomly sampled with replacement among but not within sets. Vector pairs selected for crossover swapped all elements between and including two  $\gamma_i$  randomly selected with replacement (this allowed for reversal of vector element positions during crossover; e.g.,  $\{\gamma_4, \gamma_5, \gamma_6, \gamma_7\} \rightarrow \{\gamma_7, \gamma_6, \gamma_5, \gamma_4\}$ ). The genetic algorithm terminated if a stable  $\mathbf{M}$  was found, 20 generations occurred, or if the mean  $\gamma$  fitness increase between generations was less than 0.01 (where fitness was defined as  $W_\gamma = -\max(\Re(\lambda))$  for  $\mathbf{M}$ ).

**System feasibility.** Dougoud et al.<sup>24</sup> identify the following feasibility criteria for ecological systems characterised by  $S$  interacting species with varying densities in a generalised Lotka-Volterra model,

$$\mathbf{n}^* = -(\theta \mathbf{I} + (CS)^{-\delta} \mathbf{J})^{-1} \mathbf{r}.$$

In the above,  $\mathbf{n}^*$  is the vector of species densities at equilibrium. Feasibility is satisfied if all elements in  $\mathbf{n}^*$  are positive. The matrix  $\mathbf{I}$  is the identity matrix, and the value  $\theta$  is the strength of intraspecific competition (diagonal elements). Diagonal values are set to  $-1$ , so  $\theta = -1$ . The variable  $\delta$  is a normalisation parameter that modulates the strength of interactions ( $\sigma$ ) for  $\mathbf{J}$ . Implicitly, here  $\delta = 0$  underlying strong interactions. Hence,  $(CS)^{-\delta} = 1$ , so in the above, a diagonal matrix of -1s ( $\theta \mathbf{I}$ ) is added to  $\mathbf{J}$ , which has a diagonal of all zeros and an off-diagonal affecting species interactions (i.e., the expression  $(CS)^{-\delta}$  relates to May's<sup>1</sup> stability criterion<sup>24</sup> by  $\frac{\sigma}{(CS)^{-\delta}} \sqrt{SC} < 1$ , and hence for my purposes  $(CS)^{-\delta} = 1$ ). Given  $\mathbf{A} = \theta \mathbf{I} + \mathbf{J}$ , the above criteria is therefore reduced to the below (see also<sup>26</sup>),

$$\mathbf{n}^* = -\mathbf{A}^{-1} \mathbf{r}.$$

To check the feasibility criteria for  $\mathbf{M} = \gamma\mathbf{A}$ , I therefore evaluated  $-\mathbf{M}^{-1}\mathbf{r}$  ( $\mathbf{r}$  elements were sampled i.i.d. from  $r_i \sim \mathcal{N}(0, 0.4^2)$ ). Feasibility is satisfied if all of the elements of the resulting vector are positive.

**Acknowledgements:** I am supported by a Leverhulme Trust Early Career Fellowship (ECF-2016-376). Conversations with L. Bussière and N. Bunnefeld, and comments from J. J. Cusack and I. L. Jones, improved the quality of this work.

**Supplementary Information:** Full tables of stability results for simulations across different system size ( $S$ ) values, ecological community types, connectance ( $C$ ) values, interaction strengths ( $\sigma$ ), and  $\gamma$  distributions are provided as supplementary material. An additional table also shows results for how feasibility changes across  $S$ . All code and simulation outputs are publicly available as part of the RandomMatrixStability package on GitHub (<https://github.com/bradduthie/RandomMatrixStability>).

300 **Figure 1: Example distribution of eigenvalues before (a) and after (b) separating a randomly**  
 301 **generated complex system into fast ( $\gamma = 1.95$ ) and slow ( $\gamma = 0.05$ ) component response rates.**  
 302 Each panel shows the same system where  $S = 200$ ,  $C = 0.05$ , and  $\sigma = 0.4$ , and in each case  $E[\gamma] = 1$  (i.e.,  
 303 only the distribution of  $\gamma$  differs between panels). **a.** Eigenvalues plotted when all  $\gamma = 1$ ; distributions of  
 304 points are uniformly distributed within the blue circle with a radius of  $\sigma\sqrt{SC} = 1.238$  centred at -1 on  
 305 the real axis. **b.** Eigenvalues plotted when half  $\gamma = 1.95$  and half  $\gamma = 0.05$ ; distributions of points can be  
 306 partitioned into one large circle centred at  $\gamma = -1.95$  and one small circle centred at  $\gamma = -0.05$ . In a, the  
 307 maximum real eigenvalue  $\max(\Re(\lambda)) = 0.2344871$ , while in b  $\max(\Re(\lambda)) = -0.0002273135$ , meaning that  
 308 the complex system in b but not a is stable because in b  $\max(\Re(\lambda)) < 0$ . In 1 million randomly generated  
 309 complex systems under the same parameter values, 1 was stable when  $\gamma = 1$  while 32 were stable when  
 310  $\gamma = \{1.95, 0.05\}$ . Overall, complex systems that are separated into fast versus slow components tend to be  
 311 more stable than otherwise identical systems with identical component response rates.

Figure 2: Distributions of eigenvalues before (a) and after (b) introducing variation in component response rate ( $\gamma$ ) in complex systems. Each panel show the same system where  $S = 1000$ ,  $C = 0.05$ , and  $\sigma = 0.4$ . **a.** Eigenvalues plotted in the absence of  $Var(\gamma)$  where  $E[\gamma] = 1$ , versus **b.** eigenvalues plotted given  $\gamma \sim \mathcal{U}(0, 2)$ , which increases the variance of interaction strengths ( $\sigma^2$ ) but also creates a cluster of eigenvalues toward the distribution's centre  $(-1, 0)$ . Blue ellipses in both panels show the circle centred on the distribution in panel a. Proportions of  $\Re(\lambda) < 0$  are 0.727 and 0.733 for a and b, respectively.

Figure 3: Stability of large complex systems with and without variation in component response rate ( $\gamma$ ). The ln number of systems that are stable across different system sizes ( $S$ , max  $S = 50$ ) given  $C = 1$ , and the proportion of systems in which variation in  $\gamma$  is critical for system stability. For each  $S$ , 1 million complex systems are randomly generated. Stability of each complex system is tested given variation in  $\gamma$  by randomly sampling  $\gamma \sim \mathcal{U}(0, 2)$ . Stability given  $\text{Var}(\gamma)$  is then compared to stability in an otherwise identical system in which  $\gamma = E[\mathcal{U}(0, 2)]$  for all components. Blue and red bars show the number of stable systems in the absence and presence of  $\text{Var}(\gamma)$ , respectively. The black line shows the proportion of systems that are stable when  $\text{Var}(\gamma) > 0$ , but would be unstable if  $\text{Var}(\gamma) = 0$ .

329 **Figure 4: Stability of large complex systems given  $\gamma = 1$  versus targeted  $Var(\gamma)$ .** The ln number  
 330 of systems that are stable across different system sizes ( $S$ , max  $S = 40$ ) for  $C = 1$ , and the proportion of  
 331 systems wherein a targeted search of  $\gamma$  values successfully resulted in system stability. For each  $S$ , 100000  
 332 complex systems are randomly generated. Stability of each complex system is tested given variation in  $\gamma$   
 333 using a genetic algorithm to maximise the effect of  $\gamma$  values on increasing stability, as compared to stability  
 334 in an otherwise identical system in which  $\gamma$  is the same for all components. Blue bars show the number of  
 335 stable systems in the absence of component response rate variation, while red bars show the number of stable  
 336 systems that can be generated if component response rate is varied to maximise system stability. The black  
 337 line shows the proportion of systems that are stable when component response rate is targeted to increase  
 338 stability, but would not be stable if  $Var(\gamma) = 0$ .
